ABSTRACT

The reverse water–gas shift reaction (RWGSR) using a supported ionic liquid-phase (SILP) catalyst consisting of Ru catalyst, ionic liquid (1-butyl-3-methylimidazolium chloride ([C₄mim]Cl)), and porous silica gel support, was investigated. The catalytic activity of the SILP catalyst toward RWGSR strongly depends on the kind of Ru catalyst and amount of IL. Among the three kinds of Ru catalysts ([RuCl₂(CO)₃]₂, Ru₃(CO)₁₂, and RuCl₃), [RuCl₂(CO)₃]₂ exhibits the best catalytic activity. Brunauer–Emmett–Teller (BET) surface area analysis and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) analyses of the SILP catalyst based on [RuCl₂(CO)₃]₂ and [C₄mim]Cl revealed that both the solvation of the active catalytic Ru species and the surface area of the ionic liquid phase strongly affect catalytic activity. Hence, these factors help to determine the optimum amount of [C₄mim]Cl in the SILP catalyst. The resulting SILP catalyst, with an optimum constitution, exhibited greater catalytic activity than the homogeneous system in which the same amounts of [RuCl₂(CO)₃]₂ and [C₄mim]Cl were employed. Catalytically active Ru species during RWGSR in both systems were investigated by means of electrospray ionization–mass spectrometry (ESI-MS). Interestingly, the rate-determining step in the two systems was different, implying that the silica support lowers the activation energy of the protonation reaction in the catalytic cycle. Therefore, the facilitation of the RWGSR by a SILP catalyst system can be realized by good mass transport, derived from the large surface area, as well as the effect of the silica support on activation energy. Furthermore, 20 cycles of the RWGSR using the SILP catalyst were accomplished.

1. Introduction

Synthesis gas [1,2], a mixture of carbon monoxide (CO) and hydrogen (H₂) that is industrially synthesized from natural gas or cokes, is a significant starting material in the field of C1 chemistry for the production of organic chemicals: not only methanol in large quantities, but also fine chemicals [3–10]. However, due to the highly toxic nature of CO, strict regulations have been imposed on its employment as a chemical source in industrial processes. This has necessitated the development of alternatives to CO as starting materials. Carbon dioxide (CO₂) has been recognized as a possible candidate, since it can be converted to CO by the reverse water–gas shift reaction (RWGSR: CO₂ + H₂ → CO + H₂O) and can also be easily obtained as exhaust gas from industrial and domestic buildings. RWGSR has been widely investigated by using heterogeneous supported metal catalysts such as Pt [11–14], Ni [15–18], Cu/Zn [19–23], Au [24–26], Fe [27–30] and so on. In addition to these catalyst system, RWGSR utilizing solid oxide fuel cell system has been also investigated [31]. Most of these reactions, however, are carried out at elevated temperature over 300 °C. On the

other hand, some research groups have investigated RWGSR by using transition metal complex homogeneous catalysts of Rh [32] and Ru [33–35]. These homogeneous catalysts can make RWGSR to proceed at relatively low temperature below 200 °C.

In hydroformylation [36–39], an alkene reacts with synthesis gas in the presence of a catalyst to give an aldehyde or an alcohol which have one more carbon in their chemical structure than the starting alkene. Hence, this reaction has been widely explored for application to large-scale industrial chemical processes. Recently, Tominaga endeavored to develop an environmentally-friendly hydroformylation reaction using non-toxic CO₂ instead of CO, and reported that, by using the ruthenium cluster homogeneous catalyst Ru₃(CO)₁₂, hydroformylation of various kinds of alkenes (1-hexene [40], cyclohexane [41], α -methylstyrene [42] and so on) can proceed under a H₂/CO₂ mixed gas atmosphere. In these cases, the reaction initiates from CO evolution by the RWGSR and hydroformylation subsequently occurs [41]. An attractive feature of this one-pot reaction is that hydroformylation can proceed without any purification of the mixed gas resulting from the RWGSR; thus, the RWGSR and subsequent hydroformylation occur in the same reactor

vessel, making this process a promising alternative to conventional CO-based industrial processes.

The concept of a supported ionic liquid phase (SILP), in which a thin film of an ionic liquid (IL) is immobilized on the surface of a porous support such as silica, and a homogeneous catalyst is dissolved as well as immobilized in this supported IL layer, was first proposed by Wasserscheid and his coworkers [43]. To date, they have actively investigated gas phase reactions such as hydroformylation [43–46], hydrogenation [47], the water–gas shift reaction [48,49], and hydroaminomethylation [50] in flow processes using SILP catalysts. Generally, based on design possibility, homogeneous catalysts exhibit greater catalytic activity and selectivity than heterogeneous catalysts, while the latter offer greater ease of application in chemical processes such as separation and flow processes, and are thus suitable for industrial mass production. The nature of SILP catalysts, wherein a homogeneous catalyst in the dissolved state is immobilized in a thin IL layer on a support, combines the merits of both types of catalysts. Furthermore, due to the relatively large surface area of the support and the ultra-thin thickness of the IL layer (typically, several nanometers), the interface between the IL phase and the outer part (gas phase for gas-phase reactions, or dispersion medium for liquid-phase reactions), is quite large. This is advantageous for the effective utilization of the catalyst molecule as well as mass transport. Typically, a SILP catalyst is prepared by mixing a porous support with a solution of the catalyst, IL, and co-solvent, followed by drying to remove the co-solvent. The preparation of SILP catalysts is hence simpler than that of conventional immobilized catalysts, where the catalyst molecule is chemically anchored on the surface of the support. In this study, the RWGSR using a SILP catalyst is investigated.

2. Experimental

2.1. Materials

Tricarbonyldichlororuthenium(II) dimer ($[\text{RuCl}_2(\text{CO})_3]_2$) and triruthenium dodecacarbonyl ($\text{Ru}_3(\text{CO})_{12}$) were purchased from STREM Chemicals. Ruthenium trichloride (RuCl_3) was purchased from Sigma-Aldrich. 1-Butyl-3-methylimidazolium chloride ($[\text{C}_4\text{mim}] \text{Cl}$) was purchased from Tokyo Chemical Industry. Silica gel (Wakosil C-200) was purchased from Wako Pure Chemical Industries. $[\text{RuCl}_2(\text{CO})_3]_2$ was dried at 25 °C under vacuum for one night. $[\text{C}_4\text{mim}] \text{Cl}$ was also dried at r.t. under vacuum for one night, and its water content was confirmed to be less than 200 ppm by Karl Fischer titration (Metrohm, 899 coulometer). Wakosil C-200 was heated at 500 °C for 10 h under N_2 atmosphere. $[\text{RuCl}_2(\text{CO})_3]$, $[\text{C}_4\text{mim}] \text{Cl}$ and Wakosil C-200 were stored in a N_2 atmosphere glove box (oxygen content and dew point are controlled to be less than 5 ppm and 45 °C, respectively.). Dichloromethylene (dehydrated super grade) was purchased from Kanto Chemical Co., Inc., and purified using the Nikko Hansen Glass Contour/Ultimate Solvent System 5S-AIT before use.

2.2. Preparation of SILP catalysts

The typical procedure is as follows. In the glove box, $[\text{RuCl}_2(\text{CO})_3]_2$ (60 mg, 117 μmol) and $[\text{C}_4\text{mim}] \text{Cl}$ (1.6 g) were added to a three-necked flask equipped with a stirrer bar and a silicon cap, and the flask was then taken out from the glove box. CH_2Cl_2 was collected in a Schlenk tube directly from the solvent purification system under Ar atmosphere, and 15 mL of the CH_2Cl_2 was transferred to the three-necked flask using a syringe. The resulting suspension was stirred at 30 °C until the solid dissolved completely. In the glove box, Wakosil C-200 (10.0 g) was added to another three-necked flask equipped with a stirrer bar, three-way stop cock, and silicon cap, and the flask was taken out from the glove box. The CH_2Cl_2 solution was taken out from the former three-necked flask using a syringe and placed into the latter three-necked flask, which was equipped with a N_2 -filled balloon for controlling

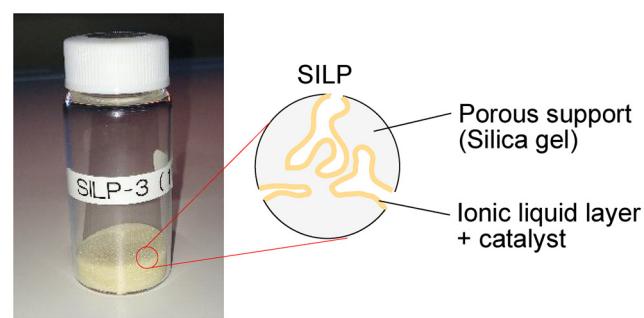

Fig. 1. Appearance of SILP catalyst and RWGSR using SILP catalyst.

internal pressure. The resulting suspension was stirred for 10 min. A distillation system, consisting of a Liebig condenser, cold trap, N_2 inlet, and vacuum pump, was connected to the three-necked flask under N_2 atmosphere, and the suspension was slowly vacuumed by means of a diaphragm pump by heating at 30 °C. After removing most of the CH_2Cl_2 , the suspension became a powder, and the three-necked flask was vacuumed using a rotary oil pump to completely remove the CH_2Cl_2 from the SILP catalyst. After drying, the prepared SILP was stored in the glove box. Fig. 1 shows the appearance of the SILP and the RWGSR using SILP in this study.

2.3. Procedure of RWGSR and evaluation of catalytic activity

The typical procedure of the RWGSR is as follows. The reaction was carried out in a 40 mL stainless-steel autoclave (Taiatsu Techno Corp. Tokyo, Japan). The SILP catalyst (1.0 g) was employed in each RWGSR test. The atmosphere of the autoclave was completely substituted to CO_2 by repeating CO_2 charge and discharge four times. Then, 2 MPa of CO_2 and 6 MPa of H_2 were introduced into the autoclave, which was tightly sealed to prevent leakage of gases during the reaction. The RWGSR was performed using an aluminum block heater (Chemist Plaza Chemi-Chemi-200, SIBATA, Saitama, Japan). The autoclave was heated to 170 °C for 30 min and maintained at 170 °C for another 10 h. The RWGSR was then immediately quenched by immersing the autoclave in cold water. The reaction gas was recovered using a sampling bag equipped with an integrated flow meter (KOJIMA ACM-1A). The concentration of CO in the recovered gas was analyzed by gas chromatography (Shimadzu, Kyoto, Japan) and the total amount of CO was calculated from the concentration and total volume of the reaction gas. Catalytic activity was evaluated by turnover number (TON) [51], which was calculated by dividing the number of moles of generated CO by that of Ru atoms in the employed catalyst.

2.4. Characterization of SILP catalysts

The surface areas and pore volumes of the SILP catalyst were determined by the nitrogen adsorption/desorption method at –196 °C using a volumetric unit (Micromeritics ASAP 2020). Prior to measurements, the sample was vacuumed at 150 °C for 10 h to remove water and volatile molecules from the surface of the sample. Infra-red (IR) measurement of the SILP catalyst was carried out by diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) technique using a Jasco FT/IR-4100 spectrometer (Jasco, Tokyo, Japan). For the measurement, Wakosil C-200, which was coated only by $[\text{C}_4\text{mim}] \text{Cl}$, was prepared and employed as the reference sample. Electrospray ionization-mass spectrometry (ESI-MS) was carried out using a Waters ZQ-2000 mass spectrometer. For measurement, Ru species were eluted from the SILP catalyst after the reaction by adding methanol, following which the resulting solution was filtered using a

polytetrafluoroethylene (PTFE) membrane filter (pore size = 0.2 µm).

3. Results and discussion

3.1. Comparison of catalysts

First, the catalytic activity of three kinds of Ru complexes, [RuCl₂(CO)₃]₂, Ru₃(CO)₁₂, and RuCl₃, was compared. SILPs were prepared using each catalyst and [C₄mim]Cl [52], and the RWGSR was performed with various reaction times. Fig. 2 shows a plot of TON as a function of reaction time. The employed catalysts exhibit quite different catalytic activities, in the following order: [RuCl₂(CO)₃]₂ > Ru₃(CO)₁₂ > RuCl₃. For Ru₃(CO)₁₂, two SILPs with the same composition were prepared and the reproducibility of their TON values was confirmed, indicating the suitability of our SILP preparation process. In the case of [RuCl₂(CO)₃]₂, the TON reached 241 within the first 10 h. However, another 30 h were required to exceed 400. No carbonaceous species other than CO was observed at this point. This convex upward behavior may be due to the equilibrium of the water–gas shift reaction. At 170 °C, the change in the Gibbs free energy (ΔG) of the RWGSR is 22.66 kJ mol^{−1}, and thus the partial pressure of CO at equilibrium can be calculated as 0.15 MPa when the initial partial pressures of H₂ and CO₂ are 6 MPa and 2 MPa, respectively. (see SI). On the other hand, a TON of 413 corresponds to a partial pressure of 0.46 MPa (see SI). The nature of SILP catalysts in batch equipment is quite complicated; hence, it is difficult to explain the above experimental results. However, it can be expected that equilibrium affects catalytic performance at 40 h. This can be also proven by the RWGSR using Ru₃(CO)₁₂. Similar TONs were obtained for the RWGSR using [RuCl₂(CO)₃]₂ and Ru₃(CO)₁₂ at 40 h, although the TON of the RWGSR using Ru₃(CO)₁₂ is only ca. two-thirds of that using [RuCl₂(CO)₃]₂ at 10 h. The catalytic activity of RuCl₃ for the RWGSR was induced by heat treatment under CO atmosphere, resulting in a comparable TON to that of the other catalysts. This may be due to the generation of [RuCl₂(CO)₃]₂ by heating RuCl₃ under CO atmosphere [53]. For subsequent analyses, the catalyst and reaction time were fixed to [RuCl₂(CO)₃]₂ and 10 h, respectively.

3.2. Optimization of IL content

To determine the optimum amount of IL in the SILP catalyst, SILP catalysts were prepared from 10.0 g of Wakosil C-200 and 60 mg of [RuCl₂(CO)₃]₂ with various amounts of [C₄mim]Cl (0–8.0 g), and abbreviated as SILP-Cl (X), where X indicates the amount of [C₄mim]Cl

employed in grams. All SILP catalysts were obtained as smooth and dry powders, except for SILP-Cl (8.0), which appeared slightly damp. The RWGSR was then carried out using these SILP catalysts. The TONs of each reaction are listed in Table 1 and plotted against the X values in Fig. 3. When [C₄mim]Cl was not employed (SILP-Cl (0)), no catalytic activity was observed, indicating that [RuCl₂(CO)₃]₂ should be dissolved in IL to act as a catalyst. With increasing [C₄mim]Cl, the catalytic activity significantly increased, and a maximum TON was achieved with SILP-Cl (1.6) (TON = 241). However, above X = 1.6, the catalytic activity decreased again and the TON was only 70 for SILP-Cl (8.0).

Results for the Brunauer–Emmett–Teller (BET) surface area analysis of SILP-Cl (X) are listed in Table 1. The specific surface area (S_{BET}) and pore volume (V_{BJH}) of Wakosil C-200 were 555 m² g^{−1} and 0.928 cm³ g^{−1} respectively, and both characteristics decreased with an increasing amount of [C₄mim]Cl, indicating that [C₄mim]Cl was impregnated in the pore of Wakosil C-200. The theoretical pore volume (V_{th}) was calculated by subtracting the mounted volume of [C₄mim]Cl from the initial pore volume of Wakosil C-200 and plotted with V_{BJH} in Fig. 4. As shown in Fig. 4, V_{BJH} is plotted beneath the line of V_{th} , indicating that [C₄mim]Cl introduced in the pore of Wakosil C-200 deposited on the bottleneck of the pore, resulting in a sudden decrease in V_{BJH} .

In the ESI-MS spectrum measured for SILP-Cl (0.04) of [C₄mim]Cl, [RuCl₃(CO)₃][−] (m/z = 292.8) is observed as the main peak (Fig. 5(a)), indicating that [RuCl₂(CO)₃]₂ is converted to [RuCl₃(CO)₃][−] during the

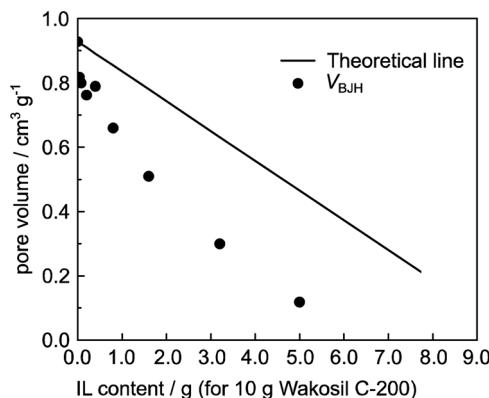

Fig. 4. Plots of V_{BJH} and V_{th} of SILP-C (X) as a function of employed amount of $[\text{C}_4\text{mim}] \text{Cl}$. Meaning of abbreviations were written in the manuscript.

preparation of the SILP catalyst. DRIFTS spectra of the SILP catalysts are shown in Fig. 5(b). The two peaks observed between 2050 cm^{-1} and 2150 cm^{-1} can be assigned to asymmetric and symmetric $\text{C}\equiv\text{O}$ vibrations of $[\text{RuCl}_3(\text{CO})_3]^-$. When the catalyst was mounted alone on Wakosil C-200 (SILP-Cl (0)), peaks corresponding to the $\text{C}\equiv\text{O}$ vibration appear at 2144 cm^{-1} and 2078 cm^{-1} . With increasing $[\text{C}_4\text{mim}] \text{Cl}$, these peaks shift to lower wavenumber and appear at 2123 cm^{-1} and 2050 cm^{-1} for SILP-Cl (1.6). However, the peak shift saturated at quantities of $[\text{C}_4\text{mim}] \text{Cl}$ above 1.6 g. The fact that only two $\text{C}\equiv\text{O}$ vibration peaks were observed for all SILP catalysts, indicates that all of $[\text{RuCl}_2(\text{CO})_3]_2$ was converted to $[\text{RuCl}_3(\text{CO})_3]^-$, even in the case of SILP-Cl (0.04) where the molar ratio of $[\text{C}_4\text{mim}] \text{Cl}$ to Ru atom in the catalyst is ca. 1, and the solvation of $[\text{RuCl}_2(\text{CO})_3]_2$ by $[\text{C}_4\text{mim}] \text{Cl}$ increases with increasing amounts of $[\text{C}_4\text{mim}] \text{Cl}$ up to SILP-Cl (1.6).

From these results, we concluded that the effect of the amount of ILs is as follows: $[\text{RuCl}_3(\text{CO})_3]^-$ can be generated from $[\text{RuCl}_2(\text{CO})_3]_2$ even when the amount of $[\text{C}_4\text{mim}] \text{Cl}$ is only 40 mg for 60 mg of $[\text{RuCl}_2(\text{CO})_3]_2$, which corresponds to a IL/Ru molar ratio of ca. 1. However, an extra amount of $[\text{C}_4\text{mim}] \text{Cl}$ is required to induce catalytic activity of $[\text{RuCl}_3(\text{CO})_3]^-$, since $[\text{RuCl}_3(\text{CO})_3]^-$ should be dissolved. Thus, the catalytic activity increases with an increasing amount of $[\text{C}_4\text{mim}] \text{Cl}$. On the other hand, when the amount of $[\text{C}_4\text{mim}] \text{Cl}$ is larger than 1.6 g, the pores of Wakosil C-200 are excessively filled with it and the catalytic activity decreases, since the reactant gas must diffuse

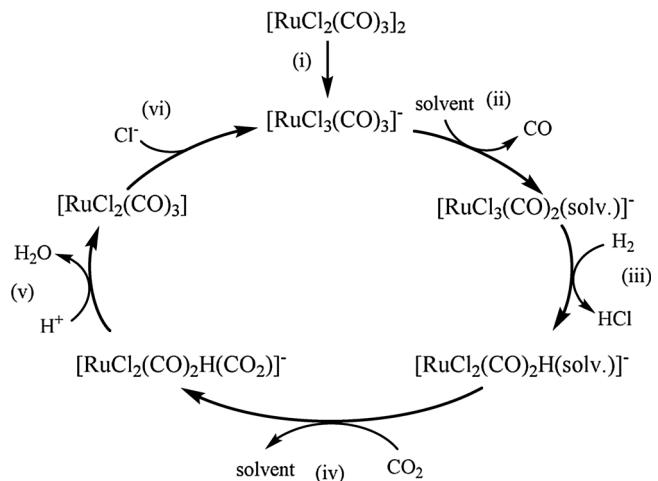

Fig. 6. Plausible catalytic cycle for RWGSR under homogeneous $[\text{RuCl}_2(\text{CO})_3]_2/[\text{PPN}] \text{Cl}/\text{NMP}$ system reported in Ref. [34]. Roman numerals with parentheses indicate each process in catalytic cycle as follows: (i) transform to catalytically active mononuclear complex, (ii) elimination of CO, (iii) hydrogenation and elimination of HCl, (iv) addition of CO_2 (v) protonation and elimination of H_2O and (vi) addition of Cl^- .

through a long distance in the IL phase to meet the catalyst molecule; this situation is disadvantageous from the point of view of mass transport. Based on these results, SILP-Cl (1.6) seems to have the optimum composition. Of course, if we change the amount of catalyst, the optimum amount of $[\text{C}_4\text{mim}] \text{Cl}$ may change. However, for all subsequent analyses, the RWGSR was performed using the SILP-Cl (1.6) catalyst system.

Although the effects of the amount of IL on the reaction rate shown in Fig. 3 appear to be in good agreement with the diffusion-reaction model [54,55], the decrease in TON under higher liquid loading conditions seems to be rather small; only about 1/3 of decrease in CO yield was observed when SILP-Cl (1.6) was replaced with SILP-Cl (8.0). This result suggests that the mass transport rate of gases in IL layer is almost comparable to the reaction rate of RWGSR even when whole pore of SILP is fully filled with IL.

3.3. Catalytic cycle of RWGSR using SILP

For the RWGSR using our SILP catalyst, the active Ru species was investigated by ESI-MS. Fig. 6 shows the catalytic cycle which was proposed by Tominaga for the RWGSR under conventional homogeneous conditions using $[\text{RuCl}_2(\text{CO})_3]_2$, bis(triphenylphosphine)imium chloride ([PPN]Cl), and *N*-methyl-2-pyrrolidone (NMP) as the catalyst, chloride, and reaction solvent, respectively [34]. In his report, the reaction solution was heat-treated under N_2 , H_2 , and H_2/CO_2 atmospheres, and catalytically active Ru species were detected by ESI-MS measurement. In this study, a similar approach was adopted for the RWGSR using a SILP catalyst. Heat treatment of SILP-Cl (1.6) was performed at 170 °C under N_2 , H_2 , and H_2/CO_2 atmospheres for 10 h. Subsequently, Ru species were eluted by methanol and negative mode ESI-MS was performed. The results are shown in Fig. 7. Before heat treatment, the main peak was observed at $m/z = 292.8$ and assigned to $[\text{RuCl}_3(\text{CO})_3]^-$, as stated in the previous section. After heat treatment under N_2 , the main peak was shifted to $m/z = 264.9$. This peak can be assigned to $[\text{RuCl}_3(\text{CO})_2]^-$, which is generated by the elimination of CO from $[\text{RuCl}_3(\text{CO})_3]^-$. After heat treatment under H_2 , the main peak appears at $m/z = 231.1$ with other peaks ($m/z = 292.8$ and 264.9) having considerable intensity. This main peak can be assigned to $[\text{RuHCl}_2(\text{CO})_2]^-$, which is generated by H_2 addition to $[\text{RuCl}_3(\text{CO})_2]^-$, following the elimination of HCl. These results are similar to those reported by Tominaga for the RWGSR under conventional homogeneous conditions [34]. Therefore, we concluded that the RWGSR using SILP-Cl (1.6) proceeds according to the same catalytic cycle as that under conventional homogeneous conditions using NMP (Fig. 6). However, a difference between the two systems was also found. When heat

treatment was performed under H_2/CO_2 mixed gas, which demonstrates RWGSR conditions, the main peak was observed at $m/z = 264.9$ and 292.8 for SILP-Cl (1.6) and the conventional homogeneous system reported by Tominaga, respectively. This indicates that the rate-determining step is different between the two systems, that is, the rate-determining step in the SILP system is H_2 addition to $[\text{RuCl}_3(\text{CO})_2]^-$ following elimination of HCl, while that in the homogeneous system is the elimination of CO from $[\text{RuCl}_3(\text{CO})_3]^-$. Additionally, other Ru species, $[\text{RuCl}_3(\text{CO})_3]^-$ and $[\text{RuHCl}_2(\text{CO})_2]^-$ were also detected in the case of the SILP system, indicating that there is no absolute difference in the activation energy of each step in the catalytic cycle for the RWGSR using SILP-Cl (1.6). On the other hand, only $[\text{RuCl}_3(\text{CO})_3]^-$ was observed for the homogeneous system, and thus CO elimination from $[\text{RuCl}_3(\text{CO})_3]^-$ must have a higher activation energy compared to other steps in the catalytic cycle. DRIFTS measurement was also performed for these SILP samples and results are shown in Fig. S1. Even for SILP system, similar relationship between ESI-MS spectra and DRIFTS spectra to that reported by Tominaga for homogeneous system [34] was observed. The difference between the SILP and homogeneous systems is further discussed in the following section.

3.4. Comparison between SILP and homogeneous system

The RWGSR was performed under homogeneous conditions and the results are listed in Table 2. When 5.0 mg of $[\text{RuCl}_2(\text{CO})_3]_2$ and 160 mg of $[\text{C}_4\text{mim}]$ Cl, which are similar amounts to those in 1.0 g of SILP-Cl (1.6), were employed (Table 2, entry 1), the TON was 125, which is approximately half of that for SILP-Cl (1.6). When 800 mg of $[\text{C}_4\text{mim}]$ Cl was employed, the TON decreased to 44 (Table 2, entry 2). This result indicates that mass transport properties affect the reaction rate.

Further investigation of the homogeneous system was performed using ESI-MS. The ESI-MS spectrum measured for the homogeneous system after the RWGSR (listed in Table 2 as entry 1) is shown in Fig. 8 with the data for SILP-Cl (1.6). For the homogeneous system, $[\text{RuHCl}_2(\text{CO})_2]^-$ ($m/z = 231.1$) was detected as the main peak (Fig. 8(a)) This result is different from that of SILP-Cl (1.6) (Fig. 8(b)), although the composition of the reaction solution (catalyst/IL) and the temperature are the same for both systems, indicating that the activation energy of the catalytic cycle changes by immobilizing the reaction solution on the silica gel surface. Since the addition of CO_2 to the metal center is generally dominated by the partial pressure of CO_2 , protonation of $[\text{RuHCl}_2(\text{CO})_2(\text{CO}_2)]^-$ must be the rate-determining step for entry 1 rather than CO_2 addition to $[\text{RuHCl}_2(\text{CO})_2]^-$. Furthermore, it can be expected that the silica gel surface facilitates protonation of $[\text{RuHCl}_2(\text{CO})_2(\text{CO}_2)]^-$. Wasserscheid and his coworkers reported that due to the more basic property of the surface, an alumina support is more suitable for the water–gas shift reaction than a silica support. We also prepared a SILP catalyst using alumina and carried out the RWGSR. In our case (the RWGSR), however, lower catalytic activity (TON = 114) was obtained compared to the SILP catalyst based on silica gel. This result is consistent with our hypothesis about the effect of the silica surface, since the more acidic nature of the silica surface (pH at point of zero charge (PZC) is ca. 2) than alumina (pH at PZC is ca. 9) is advantageous for protonation. The effect of the support on catalytic activity should be further investigated.

Thus, the enhancement of catalytic activity in the SILP system

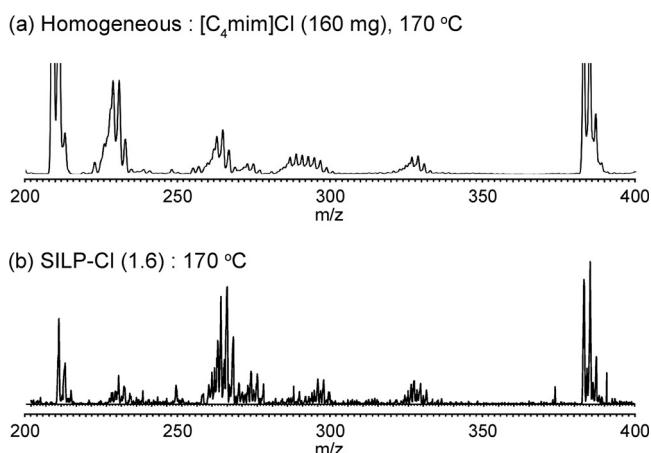

Fig. 8. Comparison of ESI-MS spectra between homogeneous system (a) and SILP-Cl (1.6) (b) after RWGSR.^a

^aReaction conditions: (a) $[\text{RuCl}_3(\text{CO})_3]_2$ (5.0 mg), $[\text{C}_4\text{mim}]\text{Cl}$ (160 mg), H_2 (6 MPa), CO_2 (2 MPa), 170 °C, 10 h. (b) SILP catalyst (1.0 g), H_2 (6 MPa), CO_2 (2 MPa), 170 °C, 10 h.

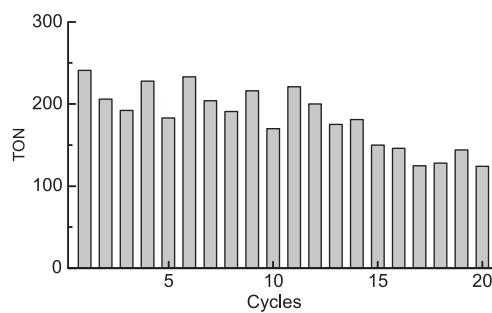

Fig. 9. Cycle performance of SILP-Cl (1.6) on RWGSR.

Reaction conditions: SILP catalyst (1.0 g), H_2 (6 MPa), CO_2 (2 MPa), 170 °C, 10 h. The autoclave was vacuumed for 30 min before each cycle.

compared with the homogeneous system is realized by a greater mass transport rate derived from the large surface area of the porous support, as well as the effect of the surface of the silica gel support, which reduces the activation energy of the process in the catalytic cycle.

3.5. Cycle performance

Cycle performance was confirmed for SILP-Cl (1.6) by recycling the catalyst as follows. After the reaction, the employed SILP-Cl (1.6) was vacuumed at r.t. in an autoclave for 30 min to remove water evolved during the previous cycle. Then, reactant gases were introduced and the RWGSR was performed again. Fig. 9 shows the results of the cycle test. In the first cycle, the TON was 241, as stated in the previous section, and the catalytic activity gradually decreased with an increasing number of cycles. However, ca. 60% of the TON was still maintained after 20 cycles, compared with the TON of the first cycle. We conclude that a fraction of the water evolved during the RWGSR still remained in the $[\text{C}_4\text{mim}]\text{Cl}$ layer due to the strong hydrophilicity of $[\text{C}_4\text{mim}]\text{Cl}$, resulting in gradual degradation of catalytic activity. During 20 cycles, the total TON reached 3600.

4. Conclusions

In this study, the RWGSR using a SILP catalyst consisting of Ru catalyst, IL, and a porous silica gel support, was investigated. The catalytic activity of the SILP catalyst strongly depends on the amount of $[\text{C}_4\text{mim}]\text{Cl}$ in the pores of the silica gel, and it was demonstrated that SILP-Cl (1.6) shows the best performance (TON = 241). Additionally,

20 cycles of the RWGSR using SILP-Cl (1.6) were accomplished. ESI-MS measurement of the SILP catalyst which was heat-treated under various atmospheres reveals that the RWGSR using the SILP catalyst proceeds according to same catalytic cycle as that under the homogeneous system NMP/[PPN]Cl. However, it also reveals that the rate-determining steps of the two systems are different. Further investigation of the homogeneous system reveals the effect of the silica support on the activation energy of the process in the catalytic cycle. Thus, we concluded that not only the high mass transport rate, but also the effect of the porous silica gel support, enhance the catalytic activity of the SILP system compared to a conventional homogeneous system. These results encourage us to further investigate SILP systems.

Acknowledgement

We greatly appreciate Dr. Marco Haumann, group leader of SILP technology in Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), for kind discussion with us.

[51] Proceeding of RWGSR can be evaluated by also amount of water generated during the reaction. Thus, in order to confirm whether hygroscopic [C₄mim]Cl layer in SILP can retain generated water or not, we performed TG-DTA and Karl Fischer titration of SILP-Cl (1.6) after RWGSR. Unfortunately, much smaller amount of water comparing with expected amount was detected in both measurements. This may be due to reaction temperature (170 °C) and overwhelming volume of space in autoclave comparing with the volume of [C₄mim]Cl in SILP-Cl (1.6).

[52] Tominaga reported that chloride based ionic liquid is preferable for RWGSR using [RuCl₂(CO)₃]₂ among halogen anion based ionic liquids in *ACS Catal.*, 3 (2013) 2865–2868. As a preliminary experiment, other than [C₄mim]Cl, SILPs were prepared by using [RuCl₂(CO)₃]₂ and some kind of ionic liquids such as 1-butyl-3-methylimidazolium bis(trifluoromethanesulfonyl)amide ([C₄mim][TFSA]), 1-butyl-3-methylimidazolium trifluoromethanesulfonate ([C₄mim][TfO]), 1-butyl-3-methylimidazolium acetate ([C₄mim][AcO]) and 1-butyl-3-methylimidazolium iodide with same composition of IL/catalyst/silica gel as SILP-Cl (1.6) and abbreviated as SILP-TFSA (1.6), SILP-TfO (1.6), SILP-AcO (1.6) and SILP-I (1.6), respectively. TON of RWGSR using these SILPs at 170 °C for 10 h under P_{CO₂}/P_{H₂} = 2 MPa/6 MPa were as follows; SILP-TFSA (1.6)=0, SILP-TfO (1.6)=0, SILP-AcO (1.6)=11 and SILP-I (1.6)=5. From these results, we decided to employ [C₄mim]Cl as ionic liquid for SILP in this study.
